On the GCC Currency Union

Weshah Razzak
Abstract

Essentially, the impact of the currency union on member countries depends on whether the common currency area is optimal in the sense that the effect of the asymmetric shocks is small, Mundell (1961). Typically, researchers use VAR of different types to analyze the data. For robustness, we use different methodologies. First, we use different estimators to estimate a small textbook model for the panel of the Gulf Cooperation Council countries (GCC) from 1970 to 2006, where the short-run equilibrium real output and the real exchange rate are determined by the intersection of the assets and goods markets equilibrium schedules. And the central bank fixes the exchange rate by keeping the money supply at a level where the domestic interest rate is equal to the foreign interest rate. Then we test for symmetry using the nonparametric Triples test, Randles et al. (1980). Third, we introduce a nonparametric multivariate statistic to test whether the variances of the shocks (the conditional variance) are equal across countries.

JEL Classification Numbers: F31, P28, C13, C33
Keywords: Optimum Currency Area, asymmetrical shocks and conditional variance,
1. **Introduction**

Bahrain, Kuwait, Oman, Qatar, Saudi Arabia and the United Arab Emirates established the Gulf Cooperation Council (GCC) in 1981. These countries share a common language, culture, and history. The GCC created a trade area, i.e., customs union and harmonized a number of regulations. Despite recent reservations made by Oman and the UAE about joining a currency union, and Kuwait’s change of its exchange rate policy from pegging to the US dollar to a basket of currencies, the GCC countries intend to go ahead with establishing a currency union in 2010. So far, most of the convergence criteria for inflation, interest rates, fiscal deficits, public debt…etc. seem to have been met (Khan, 2009).

Laabas and Limam (2002) use cointegration analysis to examine whether, or not, the GCC constitutes an Optimum Currency Area. Abu-Bader and Abu-Qarn (2006) study the shocks that affect the GCC area; they conclude that it has been subject to asymmetric supply shocks. Proponents of the Optimum Currency Area theory say that highly integrated economies should be less susceptible to asymmetric shocks. It means that even if shocks are asymmetric prior to joining the union they will by less asymmetric or symmetric in the post union period as the economies become closely integrated. Another literature has focused on whether the GCC should peg the new currency to the US dollar or to another currency, see Erbas, et al. (2001) and Abed et al. (2003). Khan (2009) examines what exchange rate regime should the union adopts.

Essentially, there are costs and benefits for joining a common currency area. These costs and benefits must be quantified and analyzed. The main cost is the loss of monetary policy independence. The effect depends on whether the currency area is optimum in the sense that the effect of asymmetric shocks is small. Presumably, researchers should test whether the shocks are asymmetric first. Then they should measure the impact of these shocks.

There are different ways to test for the symmetry of the shocks. However, most of the literature, if not all, uses different types of the VAR method. But, drawing structural inference from observed correlation can be problematic. Surely one cannot always expect to find credible identifying assumptions to identify the causal relations among an arbitrary set of variables, Hamilton (1994, p. 336). Economists have different models and make different assumptions about the relationships between variables. And, there are different methodologies to analyze the data. To ensure robustness to various models, assumptions, and methods of analyses, more of different approaches and methods to analyze an issue are preferred to less. Granger’s concept of “thick modeling”, i.e., diversification, is surely the right strategy to ensure robustness, among other things. In this paper we use three different methods to analyze issues about GCC currency area.

First, we don’t use a VAR, SVAR…etc but rather we estimate a small simultaneous equation model for the panel of the GCC countries from 1970 to 2006, where the short-run equilibrium real output and the real exchange rate
are determined by the intersection of the assets and goods markets equilibrium schedules. And the central bank fixes the exchange rate by keeping the money supply at a level where the domestic interest rate is equal to the foreign interest rate. Second, we use the nonparametric Triples test, Randles et al. (1980) and Razzak, (2001) to test for asymmetry.

Intuitively, the Triples test counts all possible triples from a sample of size \( N \) (i.e., \( \binom{N}{3} \) combinations) of the data. When most of the triples are right-skewed the data are said to be asymmetric. If \( i, j \) and \( k \) are three distinct integers such that \( 1 \leq i, j, k \leq N \), the triple of observations \( x_i, x_j, x_k \) forms a right triple or skewed to the right if the middle observation is closer to the smallest observation than it is to the largest observation. This is illustrated by:

Right triple

\[ x \quad x \quad x \]

Left triple

\[ x \quad x \quad x \]

Third, we measure and test the statistical significance of the change in the variance of the shocks (the conditional variance). Typical measures of unconditional variance such as the standard deviation measures the total variation rather than the unexpected variation. Unbiased conventional measures of fluctuations could still exhibit a substantial sampling variation. The conditional variance, however, is our preferred measure of uncertainty and it describes the variance of the shocks.

Typical tests of variance in statistics test whether the variance \( a \) is equal to the variance \( b \) against alternative hypotheses. We introduce a nonparametric multivariate test to test whether the variance of several variables, i.e., shocks in our case, are equal. This test statistic differs from others in that sense that it is a multivariate statistic, where we could test \( P \) variates in a statistic called the Sample Generalized Variance. We find significant differences across the GCC countries. Bahrain, Kuwait and Qatar are more stable than the other three with Saudi Arabia and the UAE experiencing significant conditional volatility.

Next, we present our model. In section 3 estimate the model and discuss the results. In section 4, we use the Triples test to test for symmetry. In section 5 we derive a multivariate test statistic for the generalized variance. Section 6 includes the conclusions.

2. The model

Modeling is affected by the quantity and quality of data we have. The data, which we describe next and in the appendix, are annual from 1970 to 2006. We chose to have a simple estimable model with some testable restrictions.
We estimate the model using OLS and the Generalized Method of Moments (GMM). The OLS estimator is consistent under certain conditions such as, for example, an exogeneity condition. In the presence of endogeneity it is inconsistent and inference is invalid. Generally, an instrumental variable estimator is always consistent, but inefficient. Although it is not problem-free, we appeal to the facts that the GMM estimator is appropriate when the economic model is not fully specified and that it is a robust estimator because it does not require information about the exact distribution of the error term. GMM will have a sufficiently large number of lags as instruments such that the dynamic is similar to that of a VAR.

The exchange rate and the country’s national income are determined by the intersection of assets and goods markets. To hold the domestic interest rate \( i \) at \( i^* \), the foreign level, GCC central bank’s foreign exchange intervention must adjust the money supply so that \( i^* \) equates aggregate real domestic money demand and the real money supply. Alternatively, they reset the lending rate.

In figure 1 (a), the schedule DD shows a combination of the exchange rate and output for which the goods market is in equilibrium. The schedule AA shows a combination of the exchange rate and output for which the asset market is in equilibrium. This is a straightforward textbook model.

Figure 1 (b), shows how the central bank has to adjust the money supply by buying/selling foreign assets to keep the exchange rate fixed. The foreign exchange market is in equilibrium when the interest parity condition holds, that is when the domestic interest rate \( i \) is equal to the foreign interest rate \( i^* \) plus \( \Delta S^e / S \) the expected rate of depreciation of the domestic currency against the foreign currency. \( S^e \) is the nominal exchange rate (the domestic currency price of one unit of foreign currency (i.e., an increase denotes depreciation). At zero, people expect no depreciation and the domestic interest rate equal to the foreign interest rate.

The actual real exchange rate \( Q_t \) is defined as \( (S_t P_t^*) / P_t \), where \( P_t^* \) is the foreign price, and \( P_t \) is the domestic price. There is a great debate in the economic literature about the exchange rate determination; it spans a period of more than forty years. Harrod (1933), Balassa (1964) and Samuelson (1964) show that the real exchange rate is a function of the productivity differential between tradable and non-tradable sector in the home and the foreign country. Messe and Rogoff (1983) argue that the exchange rate is a random walk process. Most asset prices follow a random walk process, which is also consistent with the efficient market hypothesis, e.g., Fama’s (1970) influential paper. But, there are also several different theories such as the monetary model and various versions of it, e.g., Mussa (1982, 1986), Frenkel’s (1967) real interest rate differential model, and Dornbusch’s (1976) overshooting model. Generally speaking, these models suggest the real exchange rate is perhaps a function of real money balances differential (money and inflation effects could be separated), output differential, and the
interest rate differential. Then we had another generation of models, where government expenditures are the main determinant of the exchange rate, e.g., Edwards (1989), Froot and Rogoff (1991) and Egert, et al. (2004).

To encompass the models of the exchange rate determination, we assume that the real exchange rate has two components: a permanent component $Q^p_t$ and a transitory component $Q^T_t$ (e.g., Meltzer (1993) and Razzak (1995)).
Further, we let the permanent component be a linear combination of last period actual real exchange rate and a vector of variables \( X_t \), which includes: \((M/P)_t, (M/P)_t^*, TOT, \hat{\delta}_t\), where \( M_t \) is money, \( P_t \) is the GDP deflator, \( TOT_t \) is the term of trade index and \( \hat{\delta}_t \) is productivity differential in tradable goods, which measures the difference in tradable sector’s productivity between each of the GCC and their trading partners, i.e., the US, Europe and Asia. It is crucial that we include the term of trade in the model. Exports are mainly oil in the GCC. Therefore, it is crucial we control for the term of trade when measuring the effect of the price of oil on the real exchange rate.iii Real per-capita output in tradable good sectors is \( \tilde{Y}_t \) for the GCC and \( \tilde{Y}_t^* \) for their trading partners. The asterisk denotes the foreign country magnitude.

Substituting in the actual real exchange rate we get:

Where the error term \( \varepsilon_{3t} \) include \( \varepsilon_{2t} \) and \( Q_t^T \). The real exchange rate is a random walk if \( \beta = 1 \).

The good market: We model real output \( Y_t \) as a function of foreign income, \( Y_t^* \) (which determines foreign demand), the price of oil \( (P_t^o S_t) \), the foreign real interest rate \( R_t^* \) and a random disturbance \( \zeta_t \) that includes uncertainty and other shocks. Real interest rates in the GCC countries are not necessarily the same because expected inflation rates might differ. There is a large literature on the relationship between the foreign interest rate and the domestic economy. The foreign interest rate could operate through the effect on the expected real depreciation as we mentioned above; exports and in the case of the GCC, oil; and financial flows. For a discussion and review of this literature see Giovanni and Shambaugh (2006).

We add a couple of equations to the model; one is the CPI, \( \hat{P}_t \), which is a weighted average of the domestic price deflator \( P_t \) and the foreign price \( P_t^* \). Non-oil production in the GCC is relatively small so we do not include the price of domestic goods. Average non-oil production as a percent of GDP in GCC in 2002, for example, was about 3.4 percent.

We obtain:

\[ Q_t = Q_t^p + Q_t^T \]
And another equation for the real money balances, which is given by:

\[ M_t^r / P_t = L(i_t^*, Y_t) \]

where \( M_t^r \) is the domestic money supply, \( P_t \) is the domestic price level, and \( Y_t \) is real GDP. Given the price level and real GDP, the equilibrium condition above determine the money supply required to fix the exchange rate permanently such that it is consistent with asset market equilibrium at a foreign interest rate.

We would have closed the model with a UIP condition equation (figure 1), where the domestic interest rate is equal to the foreign interest rate plus the expected depreciation rate. However, data for GCC nominal interest rates are not available for the whole sample, but only from the mid 1980s.

Putting all together, the model consists of the following system of equations, where the subscript \( i = 1, 2, \ldots, 6 \) GCC countries, i.e., a panel and lowercase variables denote the natural log.

\[
\begin{align*}
7 & \quad q_{it} = \alpha_{11} q_{i,t-1} + (1 - \alpha_{11})[\alpha_{12} (m_t - p_{it}) + \alpha_{13} (m_t - p_t)^* + \alpha_{14} T_o T_{it} + \alpha_{15} \tilde{d}_{it}] + \epsilon_{7it} \\
8 & \quad (m - p)_{it} = \alpha_{21} y_{it} + \alpha_{22} i_t^* + \epsilon_{8it} \\
9 & \quad \hat{p}_{it} = \alpha_{31} (p_{it}) + (1 - \alpha_{31}) (p_t^* + s_{it}) + \epsilon_{9it} \\
10 & \quad y_{it} = \alpha_{41} (p_{it}^* + s_{it}) + \alpha_{42} R_t^* + \alpha_{43} y_t^* + \epsilon_{10it}
\end{align*}
\]

The model has several asset prices: the exchange rate (endogenous), real money balances (endogenous), domestic and foreign interest rates (exogenous) and real oil price (exogenous). Real output is endogenous. All foreign variables are strictly exogenous. The term of trade is most probably exogenous. There are more exogenous than endogenous variables in the model. The model is identifiable; it satisfies the rank and order conditions.

The model predicts that an increase in domestic real money balances depreciates the real exchange rate \( \alpha_{12} > 0 \). (Positive sign denotes depreciation).

The increase in the foreign real money balances due to the central bank sells of foreign reserves for domestic money appreciates the real exchange rate \( \alpha_{13} < 0 \).

An increase in the term of trade will appreciate the real exchange rate, which is consistent with a voluminous literature showing the appreciation of the real exchange rate, \( \alpha_{14} < 0 \).

We expect that \( \alpha_{15} < 0 \), i.e., an increase in productivity appreciates the real exchange rate. In the real money balances equation \( \alpha_{21} > 0 \). Given financial innovations in the GCC countries are not expected to be as high as those in
the US we expect $\alpha_{21}$ to be greater than one perhaps. The effect of the nominal interest rate on the real money balances is negative, $\alpha_{22} < 0$.

In the real output equation, higher oil prices increase income of the GCC countries because they are major exporters of oil, so $\alpha_{41}$ is expected to be positive. The foreign real interest rate is predicted to have a negative effect on domestic production, $\alpha_{42} < 0$, see Giovanni and Shambaugh (2006). Foreign real output has a positive effect on domestic output, $\alpha_{43} > 0$.

The restriction that domestic money and foreign money coefficients in the exchange rate equation sum to zero will be tested, i.e., $\alpha_{12} + \alpha_{13} = 0$. The restriction in the price equation will also be tested, i.e., $\alpha_{31}$ and $(1-\alpha_{31})$. After we estimate the model above we solve it for the real exchange rate and compute the effect of the real oil price on the real exchange rate.

3. Data and estimation

The data we use are annual from 1970 to 2006 when the foreign country is the US. All data are in natural logs except the interest rate. Foreign real interest rates are the nominal 90-day rate minus last period inflation rate as a proxy for expected inflation. All data are from the IMF data base. The definitions are in the appendix and figures 2 to 11 plot the data. Data are available upon request.

All the data have trend except the US real interest rate (the 90-day interest rate minus last period inflation as a proxy for expected inflation). Kuwait’s GDP (figure 6) has a break during the Gulf War I in 1990. The common unit root tests that we use are not designed to handle breaks in the data; they confuse the break with a unit root. Also, most of the unit root tests have low powers, some relatively different from others. We test the data for unit root using common unit root tests for time series and panel data. We could not reject the hypothesis that the log-level data have unit roots, except for the real interest rate.

Our model which is depicted in figure 1 represents a short-run equilibrium model. For that reason we estimate the regressions in first differences (except for the US real interest rate), but there are other good reasons: First, first differenced regression is approximately the same as fixed effect models and this is precisely what we want to estimate to account for the country-effect i.e., heterogeneity. Second, we are interested in the short-run because the exchange rate and the price of oil are asset prices, which are very persistent (i.e., unit root, near random walk or random walk) so the long run is very long. Typically, when good and asset price inflations are high the lags are short relative to the lags when good and asset inflations are low. Third, to compute the Generalized Sample Variance for the residuals, they have to be I (0), which is guaranteed when we estimate our system in first differences because the levels are I (1). Fourth, we could not appeal for cointegration to run the model in levels because testing the hypothesis of no cointegration in a panel
is problematic when \( N \) (the number of cross sections) is small (6 observations only) and \( T \) (the length of time series sample) is not long.

Table 1 reports descriptive statistics for the log-differenced data (except for the real interest rates). These are period averages. The average real exchange rate depreciations are between -1 and -3 percent. But in 2006 all the currencies appreciated significantly in real terms, up to 13 percent for the UAE. Real money balance grew at rates between 6 to 8 percent on average across the GCC, just as high as the US. With exception of Kuwait, which experienced a high rate of growth in the term of trade, most GCC countries’ terms of trade grew between 3 and 5 percent on average.

All GCC countries productivity differential with their major trading partners in tradable good sectors are either zero or negatives. Relative to trading partners, the level of productivity in tradable goods in Bahrain increased in the mid 1980s, again in 2000 then flattened; increased right after the 1990s Gulf War, then flattened in Kuwait; fluctuated wildly in Oman; increased in the 1990s in Qatar then flattened; increased in Saudi Arabia over the 1970s but has been declining since 1980; and finally it has been declining all the way from 1970 in the USE. Kuwait’s real GDP has a break during the Gulf War in 1990/1991.

Most of the RHS variables in equation 7 – 10 such as money, foreign money, the term of trade, oil prices, foreign real interest rate and foreign GDP, could be assumed exogenous. For the system of equations, Least Squares method is a reasonable initial estimator, except that the real depreciation rate equation of the differenced model includes a lagged dependent variable. Thus, \( \text{cov}(\Delta \zeta_{it}, \Delta q_{it-1}) < 0 \). Thus, the coefficient \( \alpha_{it} \) is biased downward in Least Squares. We would also expect the other coefficient estimates in the real exchange rate depreciation rate to be biased and inconsistent. For this problem, for not knowing the true model or the data-generating-process, and for robustness, we also report the Generalized Method of Moments (GMM) results.

In the GMM regression, the instruments are several lags of the RHS variables because these variables are the ones that are readily available. The instruments are all in first differenced form and include a constant in every equation. For equation (7), we include trend, 8 lags of the term of trade, 4 lags of productivity differential, and 4 lags of government expenditures. For equation (8) we have 4 lags of the change in the foreign real GDP and 4 lags of the change in the foreign nominal interest rate. In equation (9) we have 4 lags of the US price level, and in equation (10) we have 8 lags of the nominal price of oil and 8 lags of the nominal exchange rate. The number of instruments and the length of the lags have well-known disadvantages so we will restrict the number of the instruments to save some degrees-of-freedom. We should interpret the coefficient estimates carefully.\(^vi\)

Table 2 reports two regressions.\(^vii\) We report Least Squares and GMM results. The effective sample sizes are different depending on the number of instruments used in the GMM regressions. All estimates are interpreted as
averages over the GCC countries and over the sample period. The real exchange rate depreciation rate does not seem persistent. The coefficient $\alpha_{11}$ is 0.30 and 0.13 in the Least Squares and the GMM regressions respectively.\textsuperscript{viii}

Real money balances depreciate the real exchange rate, i.e., the sign is positive, and significant. The size of the coefficient $\alpha_{12}$ is 0.60 (GMM) and 0.66 (Least Squares), which is relatively large. Foreign real money balances appreciate the real exchange rate, i.e., the sign is negative, and significant.\textsuperscript{ix} The coefficient $\alpha_{13}$ is $-0.78$ (GMM) and $-0.54$ (Least Squares). These coefficients sum to zero as some of the exchange rate determination models predict.\textsuperscript{x}

The term of trade also appreciates the real exchange rate, the sign of $\alpha_{14}$ is negative, and the coefficient is significant. The size is relatively larger in GMM. It suggests that a one percent increase in the term of trade over last period’s value leads the depreciation rate to fall (appreciation) by about $\frac{1}{2}$ percent in GMM and $\frac{1}{4}$ in Least Squares. This result is consistent with most of the findings in the literature on the effect of the term of trade on the real exchange rate. The GCC has experienced positive term of trade shocks lately because of the increase in the price of oil. More than 70 percent of the GCC exports are oil and gas.\textsuperscript{xii}

Even though the model has productivity differential in tradable goods only, this variable is significant and has the right sign.\textsuperscript{xii} An increase in productivity in tradable goods sector at home relative to that of the trading partners appreciates the real exchange rate. It increases the price of non-tradable goods relative to tradable good prices, and it may explain the latest increases in housing prices and services.

The income elasticity of the demand for real money balances is small in the Least Squares regression, 0.26, which is similar to estimates found in the literature for advanced countries. It is 0.43 in GMM.\textsuperscript{xiii} It is clear that the GCC banking system has come a long way. Financial services are very modern and the use of plastic cards and ATM is widespread, which might explain the surprisingly low elasticity.

The price equation is estimated in an unrestricted form and the restriction is tested. The restriction holds very well in the US dollar regressions. In GMM, the coefficients $\alpha_{31}$ (coefficient of the domestic price) and $\alpha_{32}$ (coefficient of the foreign price) sum to one.\textsuperscript{xiv} The result is self explanatory; on average more than 2/3 of the inflation in the GCC countries is imported from abroad, which is a very consistent feature of fixed foreign exchange rate regimes.

In the final equation, an increase in the real price of oil has a positive effect on output. Remember that these countries are oil producing countries, where oil and gas make up more than 2/3 of their production. Also, GDP data are expenditures side so when oil prices increase, oil revenues increase and with that expenditures, both public and private, increase. Our estimate suggests
that a 100 percent increase in the real price of oil at Dubai increases real GDP growth by 5 percent, reasonably high. A one percent increase in the US real interest rate reduces output growth in GCC by about 1 percent. The magnitude seems large. The easy monetary policy in the US, i.e., lower exchange rate and lower interest rate, might explain the expansionary phase in the GCC and the consequent inflationary pressures. The US growth rate of GDP has a significant and large effect on GDP growth in the GCC countries. These results need no further explanation.

Because Kuwait has changed it exchange rate policy twice and because it was affected by the first Gulf war in 1991, we re-estimated the model without Kuwait. We found no significant effect on the average estimated coefficients in the panel.

4. The Triples test statistic for symmetry

The literature on asymmetric shocks is quite large and most of the applications have been in the context of the EU. Asymmetry refers to a situation where the impact of a shock on a variable such as output, for example, in country A is different from its impact country B.

We use the Triples test, Randles et al. (1980) and Razzak (2001) to test the null hypothesis of symmetry against the alternative of asymmetry. It tests the hypothesis that the distribution of the data (time series or a panel), is symmetric about the unknown median \( \theta \) against a broad class of asymmetric alternatives. There are different types of asymmetries. The data possess steepness if, upon first differencing, the resultant distribution is asymmetric. De-trended data possess depth if the distribution of the levels is asymmetric. The Triples test detects asymmetry and distinguishes between positive and negative asymmetry. A detection of positive asymmetry in the first difference of a time series indicates positive steepness. This implies that, in levels, the data tend to undergo rapid increases over short period of time, and slow, gradual decreases over long periods of time. Some GDP data display negative steepness, which means that they fall rapidly, but rise very slowly.

We will test the null hypothesis of symmetry against the alternative hypothesis of asymmetry for a variety of variables. First, we test the deviations of the log level of the four endogenous variables in our system from an HP trend – detrended data; the real exchange rate \( q_{it} - HP_{trend} \); real output \( y_{it} - HP_{trend} \), real money balances \( (m - p)_{it} - HP_{trend} \) and the price \( \hat{p}_{it} - HP_{trend} \). This test would be a test of deepness. (2) We test their first difference, i.e., a test for steepness. And (3) we test the shocks of the system \( \varepsilon_{7,t}, \varepsilon_{8,t}, \alpha_{9,t} \) and \( \varepsilon_{110,t} \) from both the OLS and the GMM regressions.

We report the results in table 3. We found no evidence of asymmetry. The null hypothesis of symmetry is rejected in every case. Shocks to the real exchange rate depreciation (asset market) and shocks to real output growth (the good market) in addition to real money balances growth and inflation shocks are symmetrical across GCC countries. Surely this kind of news are
good for the optimum currency area. However, we will examine the
generalized variance of these shocks, as a block, on each of the GCC
countries.

5. The generalized conditional variability

A typical measure of unconditional variance, i.e., the standard deviation,
measures the total variation rather than the unexpected variation. Unbiased
conventional measures of fluctuations could still exhibit a substantial sampling
variation. The conditional variance is a preferred measure of uncertainty.
While ARCH, GARCH etc models are more informative about uncertainty than
unconditional variance methods, they still lack economic rationales and are
very sensitive to temporal aggregation.

Instead, we test whether the conditional variance of the model presented
earlier, which consists of four equations that proxy market fundamentals, has
remained constant against the alternative hypothesis that it increased.

For a multivariate normal variable the variance (of the population) is a function
called the Generalized Variance, which is the determinant of a matrix, \( \Sigma \) - the
variance-covariance matrix. The determinant of the sample variance matrix
\( S^2 \) is called the Sample Generalized Variance, where \( S^2 \) is the sample
covariance matrix based on sample of size \( n \).

Anderson (1958) shows that a convenient statistic for the generalized
variance is the following form of the sample generalized variance:

\[
D_k = (n-1)P \left[ \frac{|S_k^2|}{|\Sigma|} \right]^{1/p} > 0
\]

And \( k = 1, 2, \ldots, m \).

The matrix \( S^2 \) is computed by:

\[
S_{ij} = \frac{1}{n-1} \sum_{k=1}^{m} (e_{kj} - \bar{e}_i)(e_{kj} - \bar{e}_j)
\]

And \( \Sigma \) is approximately:

\[
\tilde{S}^2 = \frac{1}{N-m} \sum_{k=1}^{m} (n-1)S_{ik}^2
\]

Which is the mean of \( S^2 \).

Unfortunately, for \( P > 3 \) (in this paper we have four residuals so \( P = 4 \)), the
statistic \( D_j \) has no exact distribution so we cannot test for the significance
level. Ganadesikan and Gupta (1970) approximated the distribution by a
\( \Gamma \) (Gamma) distribution with two parameters, a shape and a scale parameter.
They showed that the $\Gamma$ distribution is best approximated when $n = 10$. In this paper $28 \leq n \leq 34$, effectively, depending on whether we have an OLS residual matrix or a GMM residuals matrix. The window for which we calculate the statistics are decided by the panel. We have 6 countries and 28 to 34 observations for each depending on whether we have OLS or GMM residuals matrix. Thus we will have 6 values for $D_k$ each represents the conditional generalized variance of a member-country of the GCC.

The two parameters defining the distribution of the statistic are the shape parameter

$$h = \frac{P(n-P)}{2}$$

and the scale parameter

$$A = \frac{P}{2} \left[ 1 - \frac{(P-1)(P-2)}{2n} \right]^{1/P}$$

To simplify the interpretation of the statistic $D_k$, we transform the $\Gamma$ distribution into a standard normal by computing the following:

$$u_k = G_{h,A}(D_k)$$

Where $G$ is the distribution function of the Gamma distribution with the two parameters above, and then the inverse of $u_k$

$$R_k(D_k) = \Phi^{-1}(u_k)$$

$R(D_k)$ and $R(S_k^2)$ are distributed standard normal and therefore the values could be $R(.) < 0 < R(.)$. A significant increase implies values of $R(D_k) > \pm 3\sigma$. The $\pm 3\sigma$ limits constitute a zone of 0.99730 intervals for the values of $R(D_k)$, which is also true for non-standard normal distribution (Tchebysheff's theorem). Values of $R(D_k)$ exceeding $\pm 3\sigma$ are considered to mean a significant change in the conditional variance.xvi We plot the 6 values in figure 12 for both the residuals of OLS and GMM.

Note that the statistics for the conditional sample generalised variance are smaller for OLS than the GMM method. The results are only quantitatively different. There are striking differences. Bahrain, Kuwait and Qatar are significantly more stable economies than the rest of the GCC, and more so in the OLS system. Bahrain and Kuwait are more stable than Qatar. Oman, Saudi Arabia and the UAE have a significantly large conditional variance. Our interpretation of these results is that although the shocks seem symmetric
across member-countries, they have significantly different variances. The four shocks together (real output growth, real depreciation rate, real money balances growth and inflation) seem to imply significantly different uncertainties.

6. Summary and more research question

In this paper, we estimated a simple simultaneous equation model, where the short run equilibrium real output and the real exchange rate are determined by the intersection of the goods and the assets markets schedules, and the central bank chose the level of the money supply such that the domestic short term interest rate is equal to the foreign (US) interest rate. We then tested the null hypothesis of symmetry against the alternative of asymmetry for the four shocks in the model, i.e., the real exchange rate, real output, real money balances, and the price level, using three different measures: deviation from HP trend, first difference, and the residuals of the system. We found no evidence of asymmetry. Finally, we calculated the conditional generalized variance of the shocks, i.e. the generalized variance of the estimated residuals. We introduced a multivariate test statistic and tested whether the conditional sample generalized variance of each member country is equal over the sample. This would tell us how individual GCC countries have been affected by the shocks. We found that Bahrain and Kuwait conditional real variability to be significantly lower from the rest of the pack.

Given the differences, one should ask more questions. First, would a historically small and stable economy (e.g., Bahrain) want to join in a currency union with another unstable economy (e.g., Saudi Arabia and UAE)? Second, would Bahrain, for example, be just as unstable as Saudi Arabia when facing the same shocks in the future where both countries are members of the same currency union? Put differently, as countries become more integrated after the union and shock effects become symmetrical as the argument goes, would the conditional variance of the shocks to the union as whole be as high as that of Saudi Arabia or as low as that of Bahrain? Three, to what extent a unified monetary policy affect the conditional variance of real shocks? These are some tough unanswered questions that one ought to answer before establishing the currency union, or not.

The assumption is that the new forthcoming currency union central bank will fix the new currency against either the US dollar or something else. One would have to wonder, what is the economic difference between the newly fixed currency to the US dollar and the old single-country currency which was fixed to the US dollar?

How much rests on the new central bank’s objective(s)? If the new central bank decides to stick to stabilizing the exchange rate it should be able to do so just in the past where each country has done successfully. However, it will experience inflationary pressures and swings in oil prices every once in a while. Recent increase in inflation did not seem to matter for most GCC countries because they are relatively wealthy. It has been a cost paid to achieve oil revenue stability. The GCC countries obviously want to fix the
exchange rate such that oil revenues are stable. Inflation hurts the poor more than it hurts the rich. Further, monetary policy will be ineffective. However, if the new central bank’s objective will be price stability (inflation or price level targeting) then it has an effective monetary policy and more work to do. To ensure domestic price stability, the exchange rate will have to be freely fluctuating, which means it will have a bigger variance because the exchange rate acts like a shock absorber, and with it swings in oil revenues. On the other hand, one would expect the variances of the shocks to converge to small magnitudes in the currency area. We believe that there has been very little research in this area, and what’s good for Europe cannot be necessarily good for the GCC.

Another important issue for research is that, mainly, the adjustments to shocks in an Optimum Currency Area take place in the labor market. A fuzzy area in this literature is the perception that the GCC labor markets are flexible (see for example, Khan, 2009) so that, presumably, labor can move freely across borders to the high labor cost area to lower wages and re-equilibrate the market. However, at least 2/3 of the labor force in the GCC countries is made of foreign workers. Foreign labor cannot move from one GCC country to another easily; they are subject to complex visa procedures. Most locals work for the government and it is highly unlikely that they move to work in another GCC country when unemployment increases in their own.

Another argument typically used for currency unions is that the single currency will reduce the cost of transaction thus it will increase trade. But trade is thin among the GCC. Would the union enhance trade? The answer is not so obvious. We are unaware of any research in this area or any back-of-the-envelope calculations.

$\bar{X}$ denotes the mean and $S$ denotes the standard deviation. The sample is 1970-2006. All data are in natural logs except for the interest rates, asterisks denote the foreign magnitudes. Nominal exchange rate $s$ defined as the domestic price of the foreign currency (USD and Euro alternatively); $p$ is the GDP price deflator (2000=100); $\hat{p}$ is the CPI (2000=100); $q$ is the real exchange rate; $m$ is money plus quasi money; $ToT$ is the term of trade (2000=100); $\hat{d}$ is tradable good productivity differential with trading partners; $\nu$ is real GDP (expenditure side); $p^0$ is the real price of oil (Dubai), and $R^*$ is the foreign 90-day interest rate. The source of the data is the IMF-IFS and the World Economic Report.

%razzak(dataset=A, variables=RESID07 RESID8 RESID9 RESID10, k=6,s=34);
i Deregulations began in January 1983. The GCC began with the removal of tariffs on products originated in the GCC member countries (products must have a minimum of 40% value added in one of the member countries and at 51% owned by a citizen of the GCC countries.) Although agricultural products, livestock; manufacturing; natural resources are exempt from duties, there are exemptions.

ii The theory does not really say what measure of money. Researchers tried almost all different definitions of money and reported mixed results, but most of the evidence of the 1970s and 1980s models of the exchange rate determination found wrong signs.

iii It is conceivable that US variables play the most important role in affecting the real exchange rates of the GCC countries. The US government massive expenditures and investments in defense could directly affect the real exchange rate in the GCC countries. We know that in countries that are major exporters of materials (primary commodity and metals) such as New Zealand and Australia, the term of trade seems to play a role in affecting the exchange rate.

iv We used the Augmented Dickey- Fuller (1984), Perron (1997), Phillips (1987), Elliott (1991), Levin, Lin and Chu (2002), Im, Pesaran and Shin (2003), Sarno and Taylor (1998) and Taylor and Sarno (1998)). We estimated a variety of specifications (constant, time trend, etc.) and examined a variety of lag structures using different Information Criteria.

v We could not allow all parameters to vary by country because we have a short sample and we would lose degrees-of-freedom.

vi For GMM see Wooldrige (2002).

vii In all regressions, we use a robust Newey-West method to calculate the variance-covariance matrix.

viii The level of the real exchange rate is a random walk, but the depreciation rate is not. The coefficients are statistically significantly different from 1. The p-value of the Wald statistic is zero.

ix Students of the exchange rate know that the literature on the monetary model of the exchange rate determination and the real interest rate differential model of the exchange rate determination is full of empirical studies that show that money has the wrong sign and that the models’ restriction do not actually hold.

x The Wald statistic’s p-values to test this hypothesis are 0.8724 and 0.6828 for GMM and Least Squares respectively.

xi We tried government expenditures, government expenditures to GDP ratio and the difference between government expenditures in the GCC countries and the US, and Europe. We found the coefficient estimates to be insignificant so we dropped these variables from the regressions.

xii Productivity in non-tradable good sectors is very difficult to measure. The productivity differential in tradable good sectors between the GCC and their major trading partners such as Europe, Asia and the US, is calculated by the IMF staff.

xiii We test whether $a_{21} = 1$; the Wald statistic’s p-value is 0.0000.

xiv The p-value of the Wald statistic is 0.1683. The restriction also holds in Least Squares; the Wald statistic’s p-value is 0.1257.
Anderson (1958) shows that the determinant of $S^2$ is proportional to the sum of squares of the volumes of all parallelopes formed by using as principle edges $P$ vectors of $X_1, X_2, \ldots, X_p$ as one set of end points, and the mean of $\varepsilon$ as the other with $\frac{1}{(n-1)^p}$ as the factor of proportionality.

A SAS – IML code to calculate the multivariate statistics for the case of three and more variables is in the appendix.

The UN (Comtrade website) and Arab Fund for Economic Development 2004 report that the share of exports among the GCC members in total exports, were 3.6% in 1990 and 5% in 2006. To put things in perspective, the same percentages for the EU were 64.9% and 66.2% respectively. Trade is thin among the GCC.
